Hypoxia and Inflammation

Holger K. Eltzschig, M.D., Ph.D., and Peter Carmeliet, M.D., Ph.D.

Mammals have oxygen-sensing mechanisms that help them adapt quickly to hypoxia by increasing respiration, blood flow, and survival responses. If an inadequate supply of oxygen persists, additional mechanisms attempt to restore oxygenation or help the body adapt to hypoxia. These other mechanisms rely on oxygen-sensing prolyl hydroxylases (PHDs), which hydroxylate prolines in the alpha subunit of the hypoxia-inducible transcription factor (HIF). This transcription factor is a heterodimer with two subunits: HIF-1α or HIF-2α and HIF-1β (or aryl hydrocarbon receptor nuclear translocator [ARNT] protein). HIF-1α is ubiquitous, whereas HIF-2α is restricted to certain tissues.

In this review, we show the ways in which the PHD–HIF system affects inflammatory processes. We discuss the regulation of immune responses by hypoxia-induced signaling, outline molecular aspects of the cross-talk between hypoxia and inflammation, and illustrate the link between hypoxia and inflammation in inflammatory bowel disease, certain cancers, and infections.

Hypoxia-Induced Inflammation

The concept that hypoxia can induce inflammation has gained general acceptance from studies of the hypoxia signaling pathway. In persons with mountain sickness, for example, levels of circulating proinflammatory cytokines increase, and leakage of fluid ("vascular leakage") causes pulmonary or cerebral edema. Increased serum levels of interleukin-6, the interleukin-6 receptor, and C-reactive protein — all markers of inflammation — were increased in healthy volunteers who spent 3 nights at an elevation higher than 3400 m. At 8400 m, healthy climbers ascending Mount Everest had severe hypoxemia (partial pressure of arterial oxygen [PaO₂], 25 mm Hg). Alveolar–arterial oxygen differences were elevated in these climbers, a finding that is consistent with subclinical high-altitude pulmonary edema. Moreover, vascular leakage, accumulations of inflammatory cells in multiple organs, and elevated serum levels of cytokines occur in mice after short-term exposure to low oxygen concentrations.

The development of inflammation in response to hypoxia is clinically relevant. Ischemia in organ grafts increases the risk of inflammation and graft failure or rejection. In patients undergoing kidney transplantation, the renal expression of toll-like receptor (TLR) 4 — an extracellular receptor for bacterial lipopolysaccharide — was shown to correlate with the degree of ischemic injury. In this study, donor kidneys with a loss-of-function TLR4 allele, as compared with donor kidneys that bore a functional allele of the TLR4 gene, had a higher rate of immediate graft function. Moreover, increases in pulmonary cytokine levels and TLR expression was shown to correlate with greater ischemic injury of transplanted lungs and loss of graft function. In the setting of obesity, an imbalance between the supply
of and demand for oxygen in enlarged adipocytes causes tissue hypoxia and an increase in inflammatory adipokines in fat. The resultant infiltration by macrophages and chronic low-grade systemic inflammation promote insulin resistance.53 Taken together, these clinical studies indicate that hypoxia promotes inflammation (Fig. 1).

**INFLAMMATION AND TISSUE HYPOXIA**

Just as hypoxia can induce inflammation, inflamed lesions often become severely hypoxic. As a result of the steep oxygen gradient between the anaerobic intestinal lumen and the metabolically active lamina propria mucosa, intestinal epithelial cells are normally hypoxic.14 In inflammatory bowel disease, not only does the entire mucosa becomes even more hypoxic,14 but surgical specimens of the inflamed intestine contain elevated levels of HIF-1α and HIF-2α.15

Contributors to tissue hypoxia during inflammation include an increase in the metabolic demands of cells and a reduction in metabolic substrates caused by thrombosis, trauma, compression (interstitial hypertension), or atelectasis (airway plugging). Moreover, multiplication of intracellular pathogens can deprive infected cells of oxygen.4 We stress that in the case of inflamed tissue, hypoxia is not a bystander but instead can influence the environment of the tissue, particularly by regulating oxygen-dependent gene expression.

**HIF AND OXYGEN SENSORS**

Cellular adaptations to hypoxia rely on the transcription factor HIF, which is inactive when oxygen is abundant but is activated in hypoxic conditions (Fig. 2).1,17 Oxygen-dependent hydroxylation of prolyl residues in HIF-1α or HIF-2α in the HIF heterodimer by PHDs creates a binding site for the von Hippel–Lindau (VHL) gene product, which is a component of the E3 ubiquitin ligase complex; the binding of the VHL gene product to HIF-1α (or HIF-2α) culminates in the destruction of the α subunit in proteasomes.18 In addition, hydroxylation of asparagyl residues in HIF-1α (or HIF-2α) by factor-inhibiting HIF — an oxygen-dependent asparagyl hydroxylase — reduces the transcriptional activity of HIF.19 The functions of both hydroxylases (PHDs and factor-inhibiting HIF) depend on oxygen.17 Germline mutations in the PHD2 gene have been found in association with familial erythrocytosis and with a syndrome of familial erythrocytosis with paraganglioma; inactivating mutations of both copies of the VHL gene cause Von Hippel–Lindau disease (which is characterized by hemangioblastomas, clear-cell renal carcinomas, and pheochromocytomas).18

HIF can be activated under normoxic conditions, which allows the initiation of an inflammatory response before tissues become hypoxic. Examples of this mechanism are the increase in HIF-1α transcription by bacterial lipopolysaccharide21 and the stabilization of HIF-1α when reactive oxygen species and reduced cellular iron inhibit prolyl hydroxylase.22,23

The phenotype of mice with HIF-1α deficiency differs from that of mice with HIF-2α deficiency, which implies that these components of the HIF transcription-factor polypeptides have different target genes.24 The HIF2A gene in certain forms of familial erythrocytosis has a gain-of-function mutation, which probably causes normoxic stabilization of the HIF-2α protein.25

**HYPOXIA SIGNALING AND NF-κB**

Members of the nuclear factor κB (NF-κB) family of transcription factors regulate inflammation and orchestrate immune responses and tissue homeostasis.26–28 Members of this family interact with members of the PHD–HIF pathway in ways that link inflammation to hypoxia (Fig. 2).29 Studies of a mouse model of inflammatory bowel disease indicate that PHDs have a regulatory role in the antiapoptotic effects of NF-κB in intestinal inflammation.30,31 The hypoxia of intestinal ischemia reperfusion activates NF-κB in intestinal epithelial cells, which in turn increases the production of tumor necrosis factor α (TNF-α), a proinflammatory cytokine, but simultaneously attenuates intestinal epithelial apoptosis.32 Additional interactions between hypoxia and inflammation are seen in the IκB kinase complex, a regulatory component of NF-κB (Fig. 2),30 and in the regulation of HIF-1α transcription by NF-κB before and during inflammation.33,34 Hypoxia amplifies the NF-κB pathway by increasing the expression and signaling of TLRs, which enhance the production of antimicrobial factors and stimulate phagocytosis, leukocyte recruitment, and adaptive immunity.35
HYPOXIA SIGNALING AND INNATE IMMUNITY

The initial defense against pathogens relies on the activation of neutrophils, macrophages, mast cells, dendritic cells, and natural killer cells. These cells of the innate immune system can rapidly eradicate pathogens and transmit signals that amplify the adaptive immune response. Myeloid cells have HIF-dependent ways of functioning in the oxygen-depleted conditions of hypoxic microenvironments. HIF-1α-null phagocytes cannot efficiently eliminate bacterial loads but instead form persistent ulcerative lesions.

HIF-1α regulates several functions of myeloid cells (Fig. 3). It allows myeloid cells to generate ATP in oxygen-deprived inflamed tissues, thereby stimulating the aggregation, motility, invasiveness, and bactericidal activity of myeloid cells. HIF-1α also prolongs the lifespan of neutrophils in hypoxic conditions by inhibiting apoptosis. In von Hippel-Lindau disease, neutrophils are characterized by reduced apoptosis and enhanced phagocytosis of bacteria under normoxic conditions, presumably owing to the failure to degrade HIF-1α.

HYPOXIA AND ADAPTIVE IMMUNITY

HIF-1α also influences adaptive immunity. Mice with HIF-1α-deficient lymphocytes have elevated levels of anti-double-stranded DNA antibodies and rheumatoid factor in serum, as well as proteinuria and deposits of IgG and IgM in the kid-
Increased production of HIF-1α in T cells induces a shift from a type 1 helper T-cell (Th1) phenotype, which enhances functions of macrophages and cytotoxic T cells, to a type 2 helper T-cell (Th2) phenotype, which inhibits Th1-mediated microbicidal actions of T cells by increasing production of interleukin-10 and decreasing interferon-γ levels. HIF also influences regulatory T cells, a specialized subgroup of inhibitory T cells. Hypoxia-induced signaling pathways stimulate the differentiation and proliferation of regulatory T cells and increase extracellular levels of adenosine, which protects tissues by restraining effector functions of T cells.

**EPITHELIAL RESPONSES TO HYPOXIC INFLAMMATION**

Activation of the PHD–HIF pathway promotes the resolution of mucosal inflammation in mice. Hypoxia-induced changes in gene expression by epithelial cells help to promote mucosal barrier function (e.g., through activation of intestinal trefoil factor) or to increase the production by the...
epithelium of antiinflammatory signaling molecules such as adenosine. These adaptive responses to hypoxia are activated during mucosal inflammation and promote the resolution of inflammatory bowel disease or acute lung injury. In mice with targeted deletion of HIF-1α in intestinal epithelia, as compared with mice that have intact HIF-1α throughout, more severe colitis develops after exposure to trinitrobenzene sulfonic acid. In contrast, in mice with inflammatory bowel disease and elevated HIF levels due to deficiency of the VHL gene, as compared with control animals, weight loss, disease activity, and histologic signs of intestinal inflammation are all reduced. In mice with colitis that is chemically induced by oral administration of dextran sulfate sodium, treatment with pharmacologic compounds that enhance stabilization of HIF reduces intestinal inflammation.

Several studies have shown that hypoxia enhances the enzymatic conversion of precursor nucleotides such as ATP, adenosine diphosphate, or AMP to adenosine, thereby elevating extracellular levels of adenosine, an antiinflammatory signaling molecule involved in restraining innate immune responses. A single-nucleotide polymorphism in CD39, an enzyme required for extracellular generation of adenosine, is associated with low levels of CD39 in a case–control study, this genetic variant was observed in patients with...
extracellular adenosine signaling that promote intestinal barrier function during inflammation and hypoxia.62,86-88 During infection with group A streptococcus or P. aeruginosa, HIF-1α in immune cells induces inflammation that helps to eliminate the patho-
Crohn's disease more frequently than it was seen in healthy subjects.\textsuperscript{61}

HIF stimulates the production of extracellular adenosine\textsuperscript{62,63} and suppresses both its uptake into the intracellular compartment and its intracellular metabolism.\textsuperscript{64,65} HIF also enhances adenosine-receptor signaling by increasing the expression on the cell surface of adenosine receptors\textsuperscript{66,67} — an effect that attenuates immune responses, vascular fluid leakage, and neutrophil accumulation in the presence of myocardial, renal, hepatic, or intestinal ischemia or acute lung injury.\textsuperscript{58,68,69} HIF-dependent induction of the axon guidance signal netrin-1 in epithelia interferes with the entry of inflammatory cells into hypoxic organs by enhancing extracellular adenosine signaling events.\textsuperscript{5} Other studies have shown that HIF also attenuates epithelial inflammation through induction of epithelial decay-accelerating factor (which clears epithelia from neutrophils)\textsuperscript{70} and induction of barrier-protective genes in the case of experimentally induced colitis or hypoxia.\textsuperscript{14,49}

**CANCER**

Concentrations of oxygen in solid tumors, as compared with those in normal tissues, are frequently reduced.\textsuperscript{71} Solid tumors contain increased levels of HIF-1α and HIF-2α, and these elevated levels correlate with cancer-related death.\textsuperscript{71} Elevated levels of HIF-1α and HIF-2α in biopsy specimens of prostate tumors have been associated with an adverse clinical course.\textsuperscript{72} Hypoxia in a solid tumor stabilizes HIF through hypoxia-dependent inhibition of PHDs. Similarly, oncogenes, or the loss of function of tumor-suppressor genes, result in the stabilization of HIF, as happens in the case of the VHL tumor-suppressor gene. In von Hippel–Lindau disease, inactivating germline mutations of the VHL tumor-suppressor gene increase the risk of renal-cell carcinoma and other tumors.\textsuperscript{73} Hypoxia and inflammation meet at several points in the setting of cancer (Fig. 4). Activation of HIF in a hypoxic tumor or in stromal cells within the tumor augments tumor vascularization.\textsuperscript{24,74} This increase in vascularization changes the morphologic characteristics of tumor vessels and their endothelial lining in ways that compromise oxygen delivery.\textsuperscript{75} In mice, haplodeletion of PHD2 attenuates tumor-vessel leakiness and vascular distortion while improving tumor-vessel architecture (“vascular normalization,” as defined by more sharply demarcated boundaries and branching points of tumor vessels)\textsuperscript{76} and tumor oxygenation.\textsuperscript{77} This change is associated with a reduction in tumor invasiveness and in the risk of metastasis.\textsuperscript{77} This finding suggests that endothelial cells use PHDs to sense and correct imbalances in oxygen delivery. Anti-PHD2 agents may offer a new approach to treating cancer, since they improve the architecture and function of tumor vessels.\textsuperscript{78}

Experimental evidence indicates that inhibition of HIF within the inflamed tumor core attenuates the growth and vascularization of tumors and enhances the sensitivity of tumors to radiation.\textsuperscript{79} In contrast, inhibition of PHD2 and stabilization of HIF within the tumor vasculature may play an important role in tumor therapy, if the means can be found to selectively direct inhibitors of PHD to the tumor vasculature and inhibitors of HIF to the hypoxic core.

**INFECTIONS**

Stabilization of HIF and induction of HIF-dependent genes occur during infections with pathogens. For example, infection with *Bartonella henselae* — the causative agent of bacillary angiomatosis — is associated with stabilization of HIF-1α and the transcription of genes that typically become transcribed in hypoxic conditions.\textsuperscript{10} In infected cells, changes in oxygen consumption, as well as cellular hypoxia and decreased ATP levels, correlate with HIF stabilization and the release of angiogenic factors during bacillary angiomatosis.\textsuperscript{10} Stabilization of HIF during infections can also be oxygen-independent.\textsuperscript{80} For example, under normoxic conditions, iron uptake by bacteria attenuates PHD activity, stabilizes HIF-1α, and induces the expression of genes targeted by HIF.\textsuperscript{81-83} Stabilization of HIF-1α has been found in liver-biopsy specimens obtained from patients with chronic hepatitis C\textsuperscript{84} and in skin-biopsy specimens obtained from patients with cutaneous infections caused by *Staphylococcus aureus*, varicella–zoster virus, human herpesvirus 8, or *Candida albicans*.\textsuperscript{85}

Pathogens may highjack the host's HIF pathway for their own advantage. *Pseudomonas aeruginosa* rapidly inactivates the adenosine that host cells produce in an HIF-dependent manner, thus depriving the host epithelium of the actions of
CONCLUSIONS

Hypoxia and inflammation are intertwined at the molecular, cellular, and clinical levels. Oxygen-sensing mechanisms and hypoxia signaling are potential therapeutic targets for the treatment of inflammatory diseases. The value of such approaches could be tested in patients with acute lung injury, myocardial ischemia, inflammatory bowel disease, or cancer. Targeting hypoxia-dependent signaling pathways could also help attenuate organ failure due to ischemia in patients undergoing major surgery or alleviate hypoxia-driven graft inflammation after solid-organ transplantation.
